## Abstract

Downstream scaling laws aim to predict task performance at larger scales from pretraining losses at smaller scales. Whether this prediction should be possible is unclear: some works demonstrate that task performance follows clear linear scaling trends under transformation, whereas others point out fundamental challenges to downstream scaling laws, such as emergence and inverse scaling. In this work, we conduct a meta-analysis of existing data on downstream scaling laws, finding that close fit to linear scaling laws only occurs in a minority of cases: 39% of the time. Furthermore, seemingly benign changes to the experimental setting can completely change the scaling trend. Our analysis underscores the need to understand the conditions under which scaling laws succeed. To fully model the relationship between pretraining loss and downstream task performance, we must embrace the cases in which scaling behavior deviates from linear trends.

## 1 Introduction

Scaling laws for language models establish that pretraining validation loss or perplexity improves reliably when increasing the size of the model, compute, and training data (Kaplan et al., 2020; Hoffmann et al., 2022; Pearce and Song, 2024). However, better pretraining loss does not always translate to better downstream performance (Magnusson et al., 2024). This gap can be caused by a variety of issues: among the best known is *emergence*, or the fact that on some tasks, models below a certain parameter scale show no trend or near-chance performance (Wei et al., 2022). Furthermore, model performance can increase and then decrease, in what is called *inverse scaling* (McKenzie et al., 2023; Wilcox et al., 2024). Despite these challenges, several works also claim

\*Equal contribution.

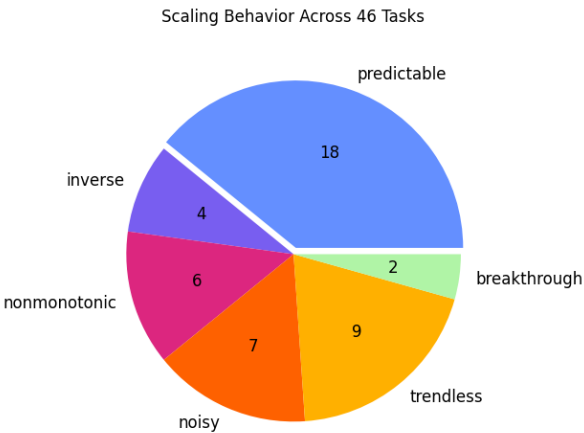

Figure 1: Revisiting the 46 tasks studied in Gadre et al. (2024), we find that only 18 tasks—or 39%—demonstrate smooth, predictable improvement (Figure 5). The other 28 tasks are shown in Figures 6 through 10, where we group them into different degenerate scaling behaviors: inverse, nonmonotonic, noisy, trendless, and breakthrough scaling. See Figure 2 for examples.

that downstream performance is roughly linear with respect to simple transformations of the pretraining loss (Huang et al., 2024; Gadre et al., 2024; Chen et al., 2025).

Thus, the extent to which downstream scaling laws work is unclear. How can downstream scaling laws follow linear forms when we know of many tasks that exhibit emergence or inverse scaling? Are these phenomena edge cases, or are they prevalent, with no established explanation? Here, we aim to clarify this confusion. We identify and consider three core factors affecting downstream scaling laws: 1) the data used for pretraining and validation, 2) the downstream task, and 3) the experimental setup. Realistic changes to each of these factors change the relationship to downstream performance, to the point that the scaling law’s functional form might no longer hold.

Core factors affecting downstream scaling laws

Why pretraining loss does not translate to good performance on certain downstream tasks?

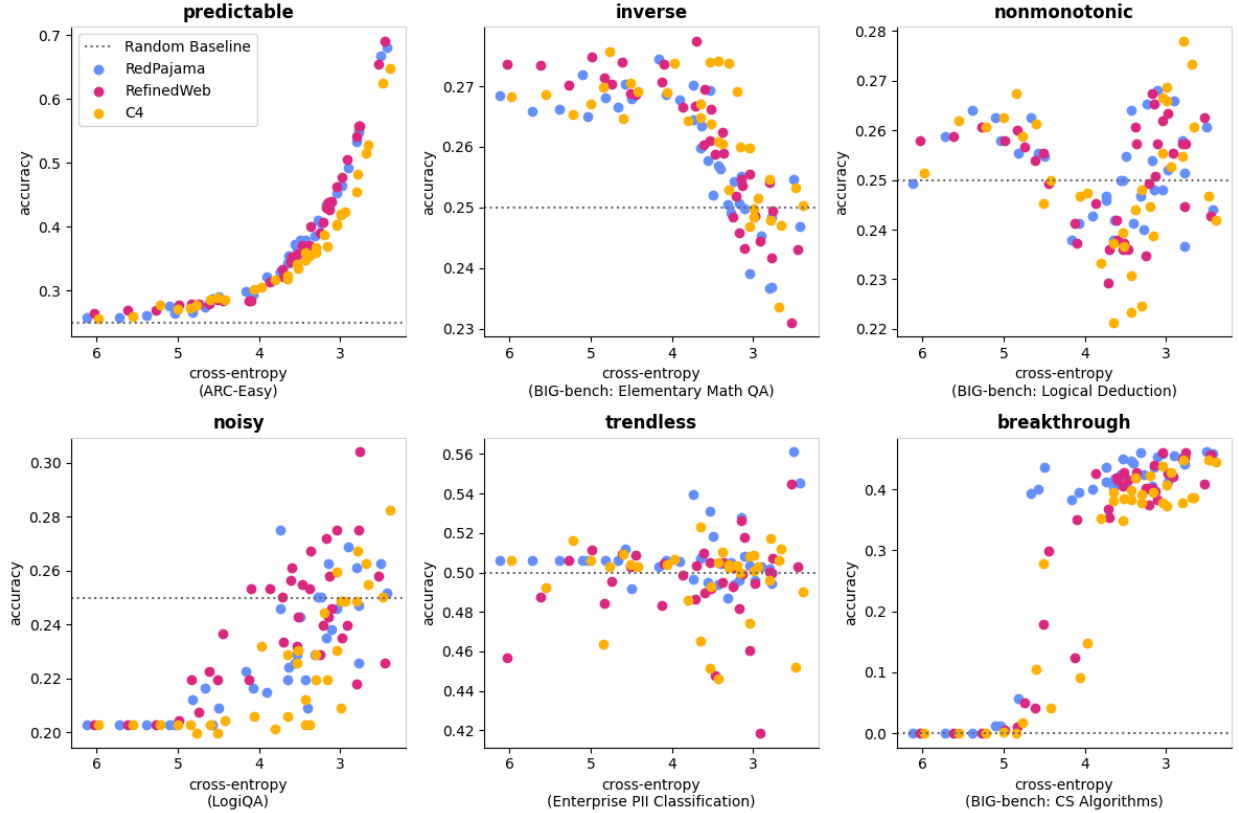

Figure 2: A taxonomy of different scaling behaviors. Predictable scaling fits closely to a linear functional form after, for example, exponentiating the cross-entropy loss. However, depending on the downstream task, models do not always improve with scale (inverse, nonmonotonic, and trendless), or the improvement might be highly noisy. The improvement might also follow a functional form that is difficult to extrapolate like a sigmoid (breakthrough).

We find that:

1. Choosing a different dataset for computing validation perplexity can flip scaling trends. For example, models trained on one pretraining corpus might appear to improve faster than another pretraining corpus, but this trend can reverse when using a different validation dataset (§3).
2. Examining a previous study (Gadre et al., 2024), we find that predictable scaling only occurs in a minority of cases: 39% of the time. This indicates that phenomena like emergence and inverse scaling are actually quite common, and can represent a significant proportion of existing downstream tasks (§4).
3. The scaling behavior observed under one experimental setting may not hold for other settings: a task with predictable scaling in one setting might show nonmonotonic scaling or even no trend at all in another setting (§5).

Our analysis suggests that scaling laws are *context-specific*. As such, we cannot assume down-

stream scaling will always be strictly linear. Rather, we need to better understand the failure modes of existing scaling laws and develop a holistic (and perhaps more complex) model of how models improve on downstream tasks.

## 2 Background

Downstream scaling laws try to extrapolate the performance of large-scale models from small-scale proxies. When successful, these scaling laws enable cost-effective experiments at the small scale that transfer to the large. Scaling laws for pretraining are well established (Rosenfeld et al., 2020; Kaplan et al., 2020; Hoffmann et al., 2022); however, the ultimate goal of language models is to perform well on downstream tasks. As such, downstream scaling laws are also of great interest.

Unlike pretraining, there is little consensus on how to approach downstream scaling laws. Early efforts attempted to predict downstream performance directly from parameter count, data, or compute (Ivgy et al., 2022; Mahmood et al., 2022; OpenAI, 2023), but downstream performance often

showed a noisy relationship to these quantities (Tay et al., 2022). Other efforts sought surrogates for scale, such as inferred latent variables (Ruan et al., 2024) or task-specific losses (Grattafiori et al., 2024; Bhagia et al., 2024), in hopes of mapping from compute to the surrogate, and from the surrogate to downstream performance.

Many works have found that downstream scaling laws are more stable when stated in terms of pretraining loss (Xia et al., 2023; Huang et al., 2024; Gadre et al., 2024; Du et al., 2024; Chen et al., 2025), the most widely used surrogate for scale. In particular, if two models have a different number of parameters or see a different number of tokens but attain the same pretraining loss, then they tend to achieve the same downstream performance (Xia et al., 2023; Gadre et al., 2024; Du et al., 2024). So pretraining loss correlates with downstream performance to a surprising degree; however, as we will show, this relationship is far from absolute.

In the best case, downstream task performance is roughly linear in some monotonic transformation of validation loss, e.g.

$$y = a \exp\{c \cdot x\} + b,$$

where  $y$  is the task performance metric and  $x$  is the validation perplexity (Gadre et al., 2024).

Linearity is amenable to extrapolation, the ultimate goal of downstream scaling laws, but linearity is known not to hold in all cases. In cases with emergent capabilities or U-shaped scaling, results at small scales cannot be used to predict capabilities at larger scales, because there exists a *structural break* (Caballero et al., 2023): the function that describes one part of the scaling curve does not apply globally, and thus one cannot extrapolate from small to large. In these cases, one cannot make the global assumption of linearity under a monotonic transformation. Emergence can sometimes be mitigated by choosing a different downstream metric (Schaeffer et al., 2023), but in other cases breakthrough improvements remain “stubbornly emergent” (Zhao et al., 2025). In general, downstream performance can behave nonmonotonically as a function of scale (Gadre et al., 2024; Magnusson et al., 2025). Li et al. (2025) found scaling laws generally difficult to reproduce and sensitive to the scaling law’s functional form, training setup, data collection, and fitting algorithm.

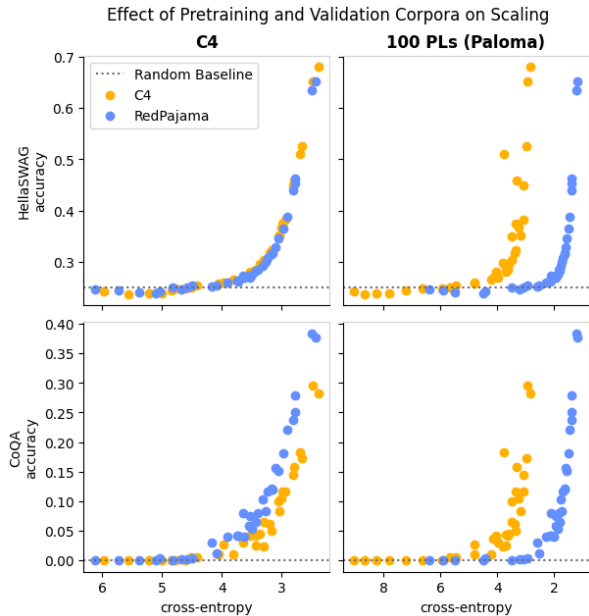

Figure 3: Choosing a different validation corpus can exaggerate or even reverse which pretraining corpus appears superior. On HellaSwag, the C4 corpus seems better than RedPajama when using 100 PLs as the validation set. Conversely, the scaling trends on CoQA for C4 and RedPajama flip when computing validation perplexity on C4 versus 100 PLs.

### 3 Scaling Laws Are Specific to the Data

In this section, we show that downstream scaling laws depend on three factors: 1) pretraining data, 2) validation data, and 3) the downstream task. It is unclear how we should choose the validation data, and yet its choice can entirely reverse which pretraining setup appears superior for a downstream task. Choosing a validation dataset is necessary to compare models pretrained on different data, as the pretraining losses are otherwise incomparable because they are taken over different distributions.

Here, we examine the evaluation results from Gadre et al. (2024), who pretrained models over different corpora. We observe how computing validation perplexity on either C4 or Paloma’s 100 Programming Languages (Raffel et al., 2020; Magnusson et al., 2024) changes downstream scaling trends on the CoQA and HellaSwag tasks (Reddy et al., 2019; Zellers et al., 2019).

**Exaggerating differences.** For the HellaSwag task with C4 as the validation corpus (top left), pretraining on either C4 or RedPajama produces the same scaling law. However, when using 100 Programming Languages (100 PLs, top right),

the scaling laws for C4 and RedPajama no longer superimpose—pretraining on C4 appears to achieve much better performance even for a worse validation loss.

**Flipping scaling trends.** Changing the task to CoQA (bottom left) also changes the scaling laws, with RedPajama now achieving better performance sooner. Even worse, changing the validation corpus from C4 to 100 PLs reverses this relationship *again* (bottom right).

Thus, whether or not better perplexity translates to better downstream performance depends on the task, the pretraining corpus, and the validation loss. Changes to any one of these three factors can reverse which pretraining setup appears superior.

#### 4 Irregular Scaling Is Common

Phenomena like emergence and inverse scaling suggest that linear scaling laws do not capture all task scaling behavior. However, it is also unclear how prevalent these phenomena are in practice. Thus, we re-examine scaling behavior on the 46 tasks tested by Gadre et al. (2024), classifying them into six categories visualized in Figure 2. We find that linear scaling actually occurs in a *minority* of cases in their setting: 39% of the time (Figure 1). For some experimental setups, non-linear scaling is actually the norm. Are the experimental choices of Gadre et al. (2024) abnormal? On the contrary, all three of pretraining corpora, validation datasets, and downstream tasks are from well-known sources in the literature. Downstream tasks are comprised of established evaluations like BoolQ, HellaSwag, and BIG-Bench (Clark et al., 2019; Zellers et al., 2019; Srivastava et al., 2023). Irregular scaling occurs within popular tasks and is easy to find.

#### 5 Scaling Behavior Is Not Always Robust

Finally, we show that conclusions about scaling laws may not generalize across settings: setups with the same validation data and downstream tasks may observe entirely different scaling trends. To show this, we take the 10 overlapping tasks between Gadre et al. (2024) and Magnusson et al. (2025). These authors consider several of the same pretraining corpora and downstream tasks; however, their implementation details differ (see Appendix D). For example, Gadre et al. (2024) use fewer answer choices for Commonsense QA.

Thus, we might expect to see quantitative differences in some of their scaling laws, but—what is more surprising—is that we also see *qualitative* changes in their scaling behavior.

To plot downstream performance on the same axes, we evaluate all models from Gadre et al. (2024) and Magnusson et al. (2025) on the same validation corpus (C4). For Magnusson et al. (2025), which does not use C4, we evaluate 200 released checkpoints, which vary in their pretraining setup:<sup>1</sup>

1. Parameters: {20M, 60M, 150M, 300M, 1B}.
2. Pretraining corpus: {Dolma, C4, DCLM-Baseline, RefinedWeb (Falcon), FineWeb-Pro} (Soldaini et al., 2024; Raffel et al., 2020; Li et al., 2024; Penedo et al., 2023b; Zhou et al., 2025).
3. Training steps: from 5,000 to 40,000, in intervals of 5,000.

Out of the 10 overlapping downstream tasks, Figure 4 shows three that produce different scaling trends between setups. In both setups, MMLU shows a positive trend; however, the noisiness and shape of that trend differs greatly. At an even greater extreme, CommonsenseQA’s scaling behavior qualitatively changes: while CommonsenseQA shows nonmonotonic scaling in Gadre et al.’s (2024) results, it exhibits a clean scaling law with Magnusson et al.’s (2025). On the other hand, in Magnusson et al.’s (2025) results, BoolQ’s scaling law appears trendless; however, this lack of trend comes from the models spanning too small a validation loss range. Since Gadre et al.’s (2024) models cover a wider range of validation losses, the trend more clearly emerges. Thus, scaling behavior can fluctuate, even between controlled studies on pretraining corpora.

#### 6 Discussion

Given the cost of training modern foundation models, scaling laws have become an invaluable tool for making informed modeling decisions. Scaling laws enable us to extrapolate results where compute costs would otherwise make extensive experimentation infeasible. However, extrapolations are only worthwhile when their assumptions are faithful to the data.

<sup>1</sup>The 20M models are the smallest models in Magnusson et al. (2025) and have the highest cross-entropy loss.

Perplexity may or may not be useful for downstream tasks

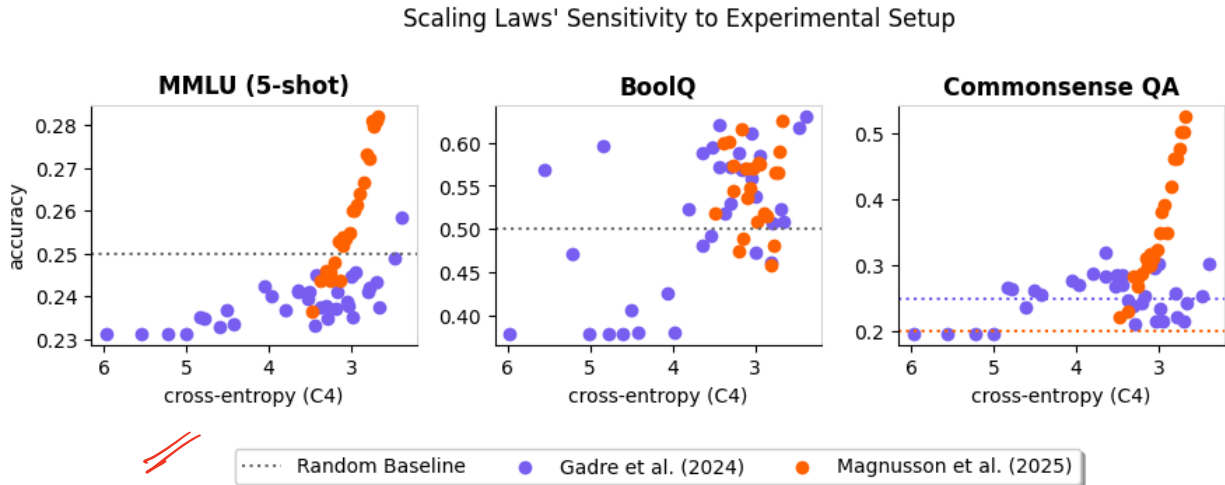

Figure 4: Scaling behavior changes depending on the experimental setting. [Gadre et al. \(2024\)](#) and [Magnusson et al. \(2025\)](#) both train language models on C4 and evaluate on MMLU, BoolQ, and Commonsense QA. Still, they differ in their details, such as model architecture, task formatting, or the number of answer choices (in the case of Commonsense QA). *Even with the same corpora and downstream task, scaling trends can be dramatically different.*

As practitioners of scaling laws, we must realize that predictable scaling laws often exist, but one cannot assume that they hold for all contexts. Even if scaling is stable on the same task for the same validation data, other aspects of the experimental setup might change the scaling behavior (§5). To some extent, scaling laws are *investigator-specific* (Li et al., 2025), and so each investigator must verify the scaling law’s presence with visualizations and regression diagnostics (Shalizi, 2015).

For researchers, downstream scaling laws offer many fascinating new directions. Empirically, we need better ways to stabilize scaling laws and detect when irregular scaling might occur. We must understand the factors affecting scaling laws, and what parts of the experimental setup must remain constant for linear scaling laws to hold. Theoretically, we need a model for why predictable scaling occurs (Hutter, 2021), and a core goal of such a theory should be explaining exactly the cases in which scaling is unpredictable.

## 7 Conclusion

In this work, we surveyed where downstream scaling laws break down. Depending on the pretraining corpus, validation corpus, or downstream task, scaling laws can change. Better perplexity does not always translate to better downstream performance (§3); *perplexity is not all you need*. Even when holding pretraining and validation data the same, more often than not a predictable scaling law does not exist at all (§4). Irregular behaviors like

nonmonotonic, trendless, or breakthrough scaling are all common; one must establish predictable scaling for the given task before relying on it. Finally, seeing predictable scaling in one experimental setup does not guarantee it for another (§5). Until we better understand why predictable scaling arises and its sufficient conditions, investigators must verify scaling laws in their own settings.

## Limitations

Our work uses data and model checkpoints from existing studies ([Gadre et al., 2024](#); [Magnusson et al., 2025](#)). While this is sufficient for the counterexamples featured in this work, there may be unknown biases shared between these two projects that we have missed.

In addition, our study establishes that downstream scaling laws are unreliable *under current practice*. Neural networks used to be notoriously difficult to train; however, as understanding developed around how to architect, initialize, and optimize them, training neural networks became routine and reliable. In a similar way, it is possible that the difficulties discussed here may be overcome by better techniques for measuring and estimating scaling laws. We hope the challenges we identify here inspire researchers to search for them.

# Summary

## Introduction

- Scaling laws for language models have been studied in depth and are well-established to an extent. Increasing the size of the model, data, and compute tends to increase the performance of LLMs.
- Though scaling laws give a reliable performance trend for pretraining, better pretraining loss or perplexity does not always translate to better downstream performance.
- As a result, the downstream performance relationship is not always clear, and performance gaps are caused by several issues, with emergent behavior being the most prominent one.
- The authors identified three major factors that directly affect downstream scaling laws, namely: i) datasets used for pretraining and validation, ii) the downstream task, and iii) the experimental setup.
- The authors discovered that changes to any of these factors change the downstream scaling performance, and in some cases, the change can be so drastic that the scaling may no longer be functional.

## Background and Past Works

- Many works have found that downstream scaling laws are more stable when stated in terms of pretraining loss. In particular, two models with different numbers of parameters but the same pretraining loss tend to achieve the same downstream performance.
- In the best-case scenario, downstream task performance is roughly linear in some monotonic transformation of validation loss. For example,  $y = a \exp(c \cdot x) + b$ , where  $y$  is the task performance metric and  $x$  is the validation perplexity.
- Cases where we witness emergent behaviors show a structural break, and hence, extrapolation does not work.

## Scaling Laws Are Specific to the Data

- Downstream scaling laws are dependent on three factors: 1) pretraining data, 2) validation data, and 3) the downstream task.
- What validation to choose is use-case dependent, but a necessary evil to compare two models, especially when they are pretrained on different data distributions.
- For the HellaSwag task with C4 as the validation corpus, pretraining on either C4 or RedPajama produces the same scaling law. However, when using 100 Programming Languages as the validation set, pretraining on C4 appears to achieve much better performance, even with a worse validation loss.
- For other tasks like CoQA, RedPajama achieves better performance. Also, changing the validation set from C4 to 100 PLs reverses this relationship.
- Hence, better perplexity during pretraining may not translate to better downstream task performance, and is dependent on the downstream task, the pretraining corpus, and the validation loss.

## Irregular Scaling Is Common

- Linear relationships do not capture irregular scaling behaviors like inverse scaling or structural breaks that occur with emergent behaviors.
- How often does linearity hold? To find this out, the authors re-examine scaling behavior on the 46 tasks, classifying them into six categories.
- They find that linear scaling occurs in a minority of cases in their setting: 39% of the time. For some experimental setups, non-linear scaling is the norm.

## Scaling Behavior Is Not Always Robust

- Scaling laws may not generalize across settings. Setups with the same validation data and downstream tasks may observe entirely different scaling trends.
- Differences in scaling law behavior may be both quantitative and qualitative. Here is an example showcasing the same:
- There are cases where scaling laws hold and cases where they do not. To some extent, scaling laws are investigator-specific, and so each investigator must verify the scaling law's presence with visualizations and regression diagnostics.

## Conclusion

For better downstream task performance, perplexity is not all you need!

## A Scaling Behavior Examples

Figures 5 through 10 each presents all the tasks studied in Gadre et al. (2024) that demonstrated a specific scaling behavior.

## B Sensitivity to Experimental Setups

Figure 11 shows how the scaling laws change between the experimental setups of Gadre et al. (2024) and Magnusson et al. (2025) across 10 tasks.

## C The Effect of the Pretraining and Validation Corpora

Figure 12 compares how the task, the pretraining, and validation corpora affect the scaling curve. For ease of visualization, we show only the effect on the tasks with the cleanest, most predictable scaling laws.

## D Data Sources

The first set of results comes from Gadre et al. (2024) and is available<sup>2</sup> under the MIT License. Gadre et al. (2024) pretrain transformer language models across different scales on several different corpora (e.g., C4 (Raffel et al., 2020), RedPajama (Weber et al., 2024), and RefinedWeb (Penedo et al., 2023a)). For each model, they compute its validation loss on these and other corpora, and evaluate the model with few-shot prompting across 46 tasks using LLM Foundry.<sup>3</sup>

The second set of results comes from Magnusson et al. (2025) and is available<sup>4</sup> under the ODC-By License. Magnusson et al. (2025) also pretrain transformer language models but they choose different architectural details than Gadre et al. (2024) and use the C4 and RefinedWeb versions from Dolma 1.7 (Soldaini et al., 2024). They pretrain models across these and other corpora and evaluate them with few-shot prompting on 10 different tasks via OLMES (Gu et al., 2025).<sup>5</sup>

The evaluation harnesses, LLM Foundry and OLMES, have some important differences. LLM Foundry ships with its own versions of tasks’ datasets. For some tasks (e.g., Commonsense QA and SIQA), it changes the number of answer choices, thus the random baseline can change

between the different versions and we have indicated this in the appropriate figures. LLM Foundry also varies the number of shots depending on the task, whereas OLMES uses 5 curated examples for each one. Other differences include the task formulation (whether to use multiple-choice or cloze format) and implementation details such as the prompts.

Finally, LLM Foundry’s version of SIQA had an error where the gold labels were incorrect.<sup>6</sup> This issue was fixed in LLM Foundry v0.5.0;<sup>7</sup> however, Gadre et al. (2024) used v0.4.0 for at least some of their experiments.<sup>8</sup> As a result, we do not examine SIQA in our analyses, although Figure 11 in Appendix B includes SIQA for completeness.

## E Reproducibility

We augment the results from Magnusson et al. (2025) by evaluating their models on C4’s validation data. This additional information enables us to compare scaling laws from Magnusson et al. (2025) and Gadre et al. (2024).

To compute the validation loss, we ran the DataDecide (Magnusson et al., 2025) models from HuggingFace using ai2-olmo (<https://github.com/allenai/OLMo>), computing the perplexity on C4’s validation split using a batch size of 64. For inference, we used a combination of A100 and H100 GPUs with 32 GB of CPU RAM. Running inferences over the C4 validation set took approximately 10 minutes.

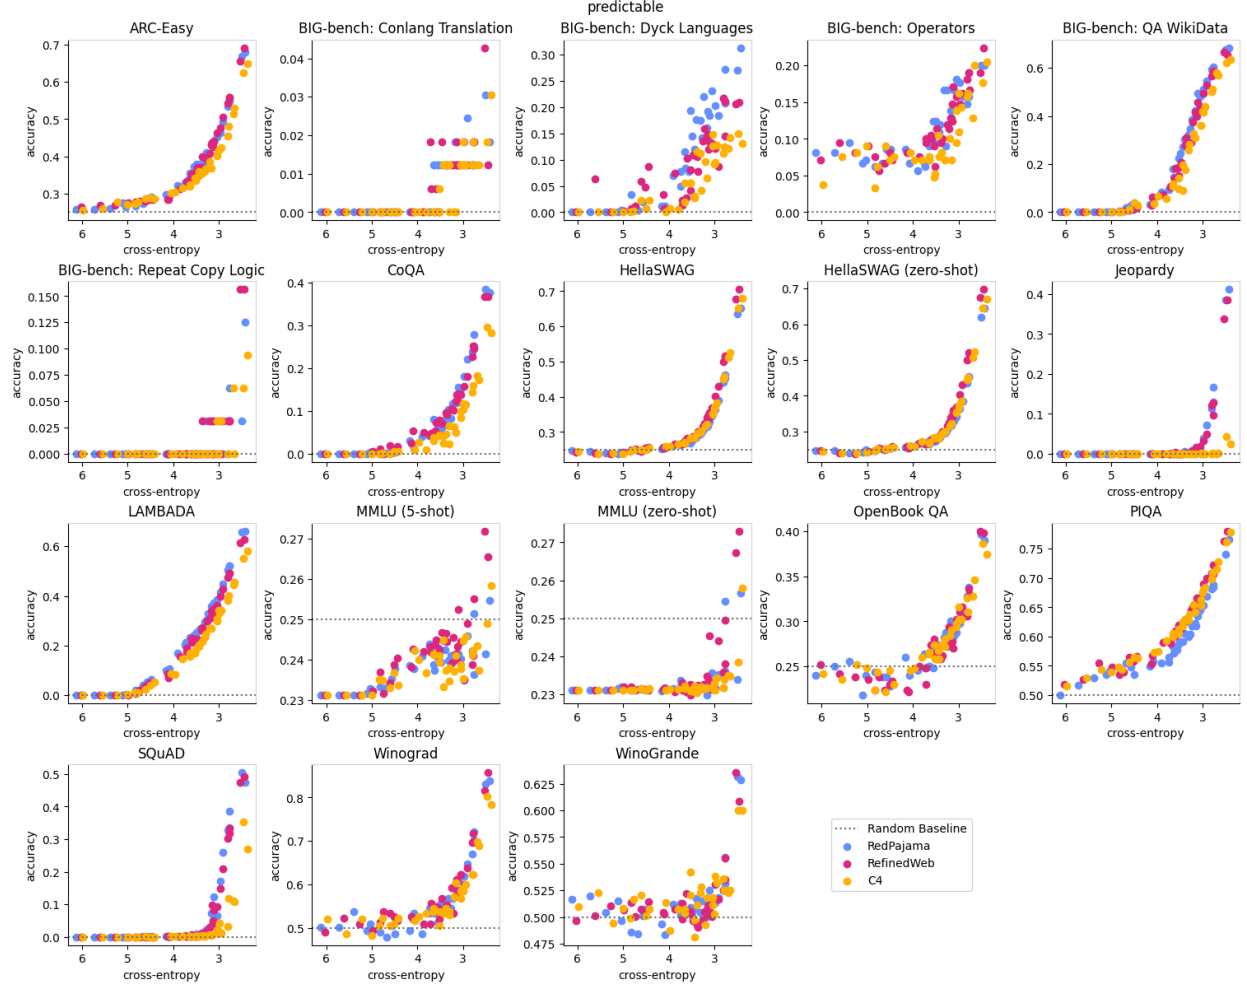

Figure 5: The 18 tasks in [Gadre et al. \(2024\)](#) with scaling behavior well-described by a linear scaling law after transforming the cross-entropy loss.

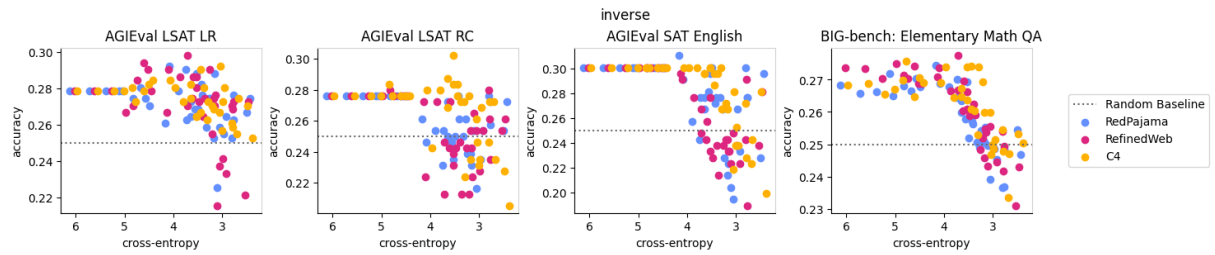

Figure 6: Tasks in [Gadre et al. \(2024\)](#) with inverse scaling.

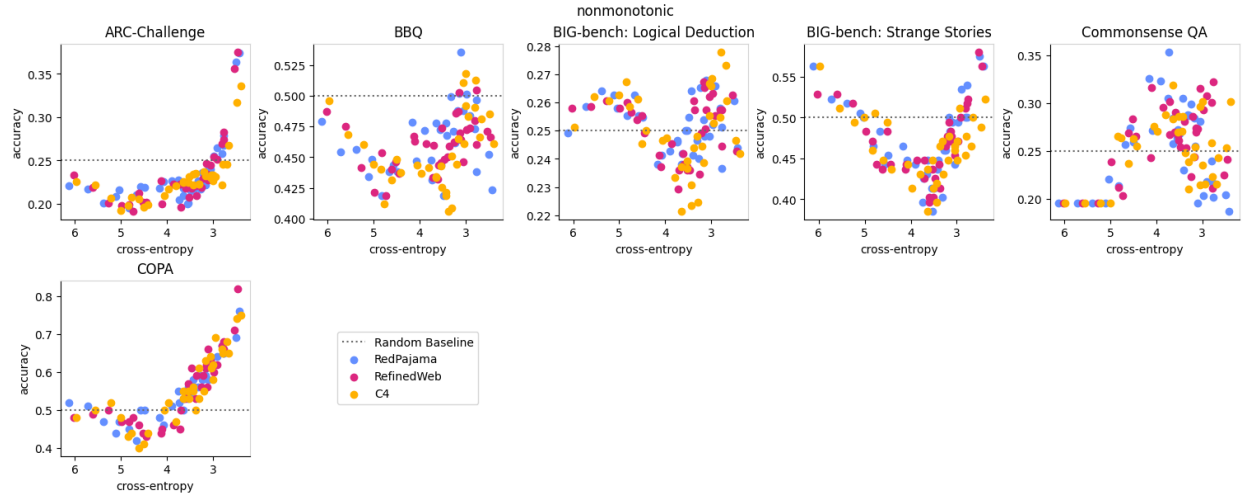

Figure 7: Tasks in Gadre et al. (2024) with nonmonotonic scaling.

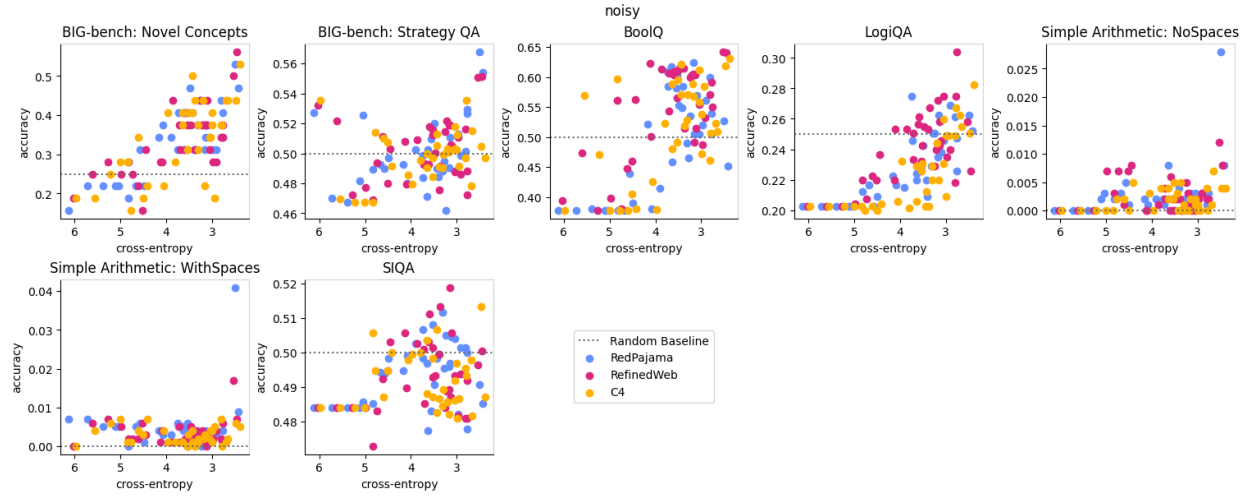

Figure 8: Tasks in Gadre et al. (2024) with noisy scaling.

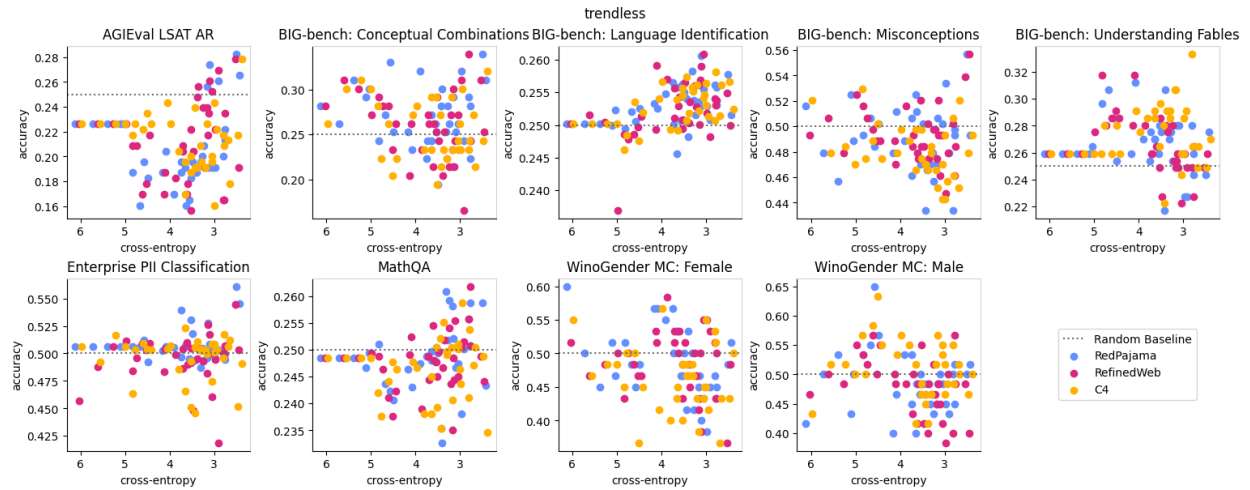

Figure 9: Tasks in Gadre et al. (2024) with no clear scaling trend.

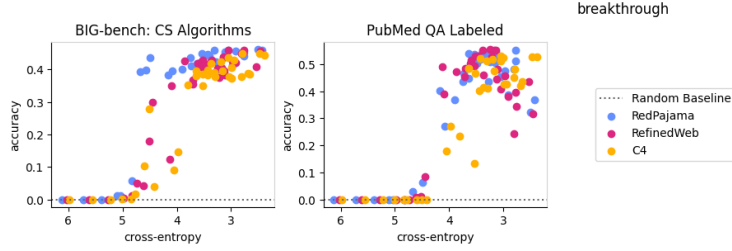

Figure 10: Tasks in [Gadre et al. \(2024\)](#) where scaling behavior is better described by a sigmoid functional form.

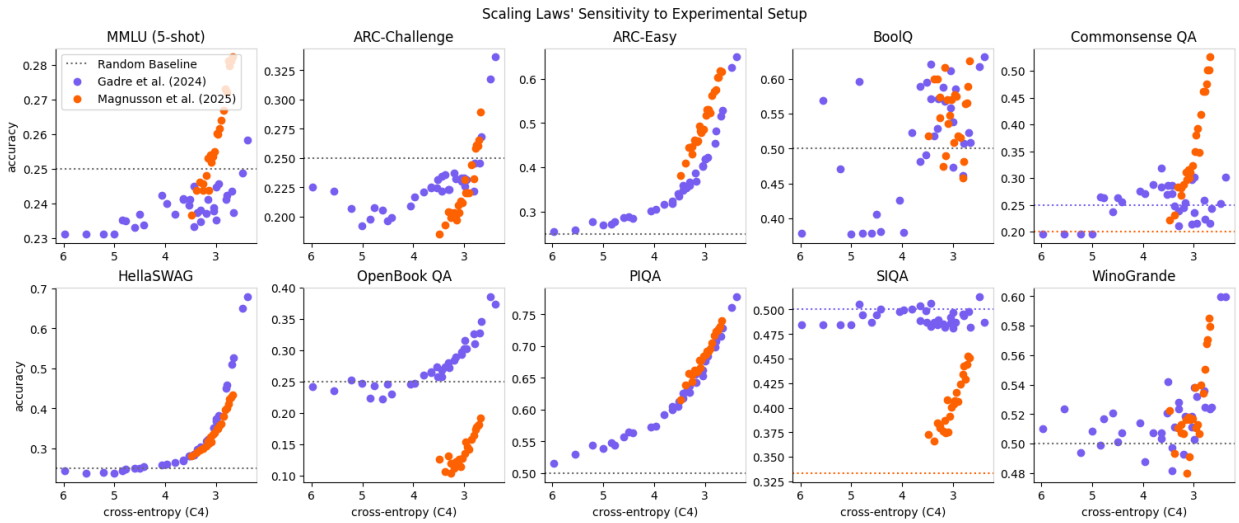

Figure 11: A comparison of scaling in the experimental setups of [Gadre et al. \(2024\)](#) and [Magnusson et al. \(2025\)](#). Both trained language models on C4 and evaluated via few-shot prompting on the tasks above; however, their experimental setups differ: architectural details, prompts, number of shots, task format, and in some cases the number of answer choices (Commonsense QA and SIQA). Such experimental details totally change scaling behavior.

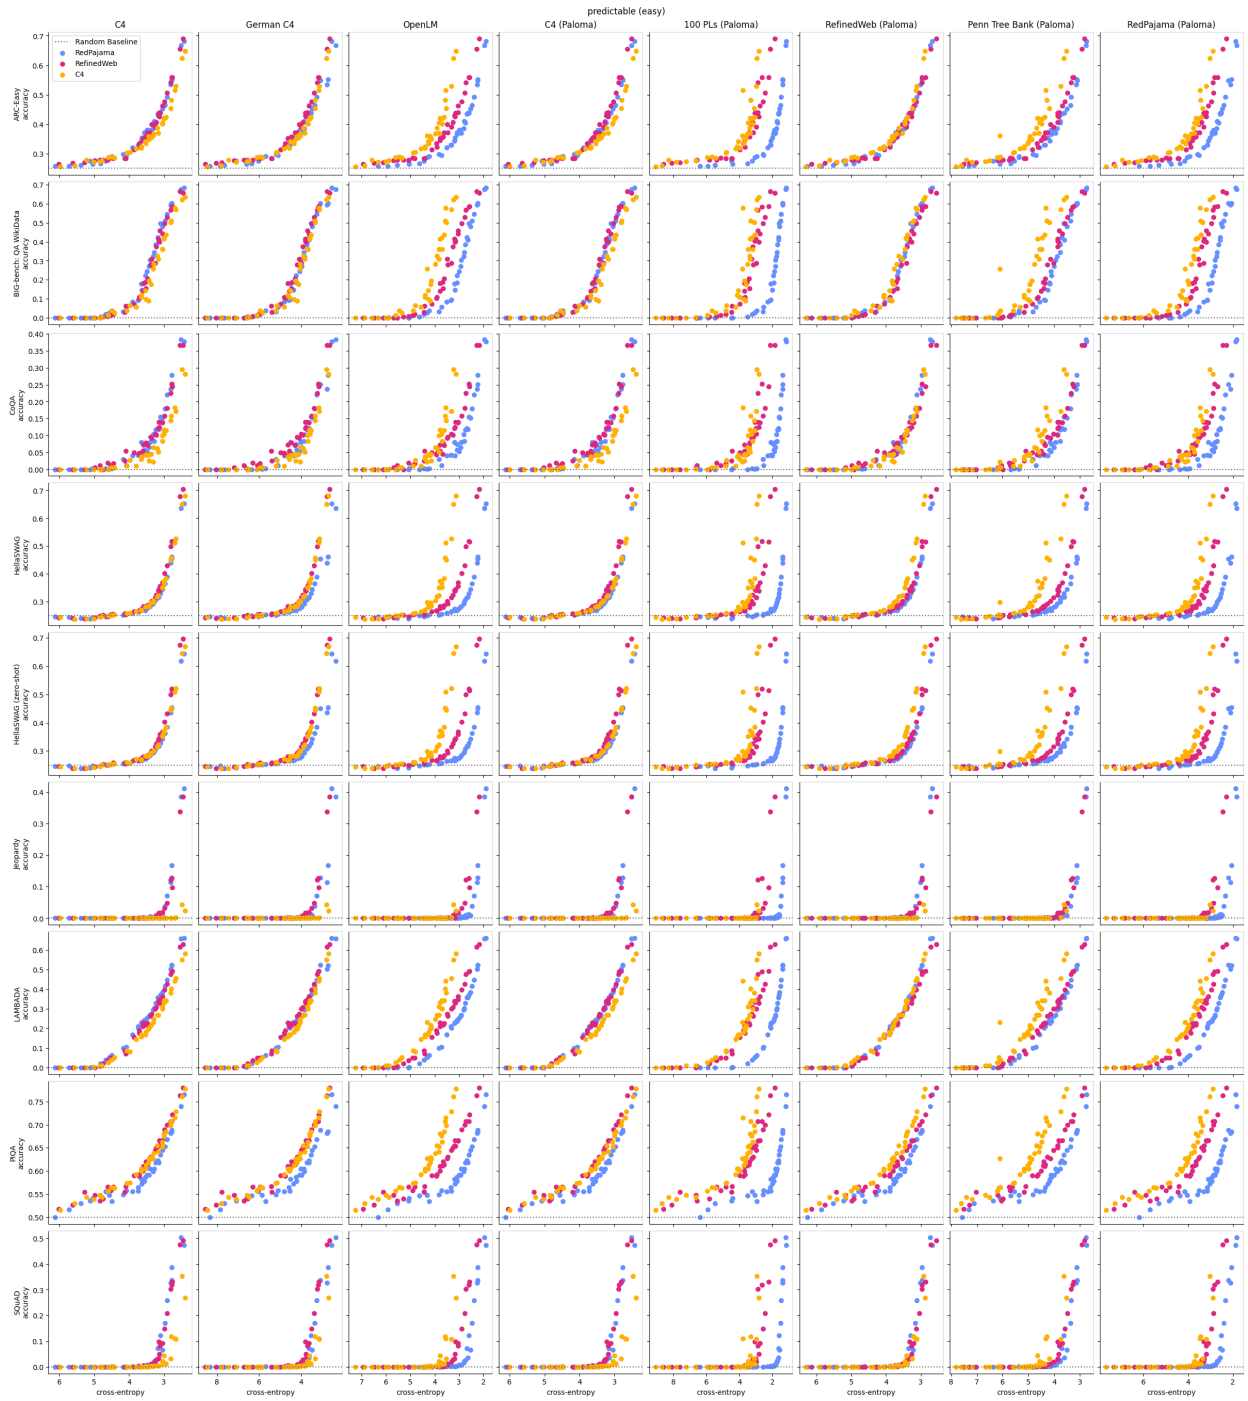

Figure 12: Different pretraining corpora will appear to be the best for downstream tasks, depending on choice of validation dataset.
